# Report Practical(Assignment 3)

#### Team members:

Fares Ben Slimane Parviz Haggi Mohammed Loukili Jorge A. Gutierrez Ortega

April 22, 2019

#### Abstract

This report includes our solutions to the problems of the 3rd practical assignment. It consists of three sections: In Section 1 we implement the original GAN and WGAN with gradient penalty along with some experimentation. Section 2 is about the implementation and experimentation of the VAEs. The last section (3) includes experimentation and evaluation of the generative models' ability to generate realistic-looking images. In each case, our code is uploaded to the following Github repository [1]

## Problem 1

In this problem we are using a GAN discriminator to estimate the Jensen Shannon divergence (JSD) and a the Wasserstein Distance (WD). We implement the discriminator/critic using a multi-layer perceptron that we can initialize to either have an output  $y \in [0,1]$  (sigmoid activation) or an output  $y \in \mathbb{R}$  (no activation). The architecture consists of two hidden layers with 64 and 128 output units respectively. We use ReLU activation function in the hidden layers.

1. In this section, we implement a function to estimate the JSD. Using our MLP with sigmoid activation at the output we optimize the following objective function:

$$\arg\max_{\theta} \left\{ \log 2 + \frac{1}{2} \mathbf{E}_{x \sim p} [\log(D_{\theta}(x))] + \frac{1}{2} \mathbf{E}_{y \sim q} \log(1 - D_{\theta}(y))] \right\}$$

At its optimum, the objective function estimates the JSD between the distributions given by p and q. An overview of the implementation can be seen below. The full code is available in the file **density\_estimation.py** under our github repository [1].

```
#Implementation of the JSD

optimizer.zero_grad()

p = torch.cat((p1,torch.rand(batch_size,1)),1).to(device)

q = torch.cat((phi*torch.ones(batch_size,1)),t)

orch.rand(batch_size,1)),1).to(device)

Dp = net(p)

Dq = net(q)

loss = -(math.log(2.) + (1/2.)*torch.mean(torch.log(Dp)) +
```

```
11  (1/2.)*torch.mean(torch.log(1-Dq)))  12 loss.backward() optimizer.step()
```

2. In this section, we implement a function to estimate the WD. In this case we use our MLP without activation function, so it has an output of a real valued scalar. Here we optimize the following objective function:

$$\arg\max_{\theta} \mathbf{E}_{x \sim p}[T_{\theta}(x)] - \mathbf{E}_{y \sim q}[T_{\theta}(y)] - \lambda \mathbf{E}_{z \sim r}(||\nabla_z T_{\theta}(z)||_2 - 1)^2.$$

r is the distribution over z = ax + (1 - a)y, where  $x \sim p$ ,  $y \sim q$  and  $a \sim U[0, 1]$ .

At it's optimum, this objective function estimates the WD between the distributions given by p and q. The following portion of the code shows the implementation of the optimization. The full code is also available in our repository [1]

```
#Implementation of the WD
  optimizer.zero_grad()
5 p = torch.cat((p1,torch.rand(batch_size,1)),1).to(device)
6 q = torch.cat((phi*torch.ones(batch_size,1),
                          torch.rand(batch_size,1)),1).to(device)
8 \text{ Dp} = \text{net}(p)
p Dq = net(q)
10 # gradient penalty
11 a = torch.rand(batch_size, 1).expand(batch_size, 2).to(device)
r = a*p + (1-a)*q
13 r.requires_grad = True
Dr = net(r)
gradients = torch.autograd.grad(outputs=Dr, inputs=r,
                   {\tt grad\_outputs=torch.ones(batch\_size\ ,1).to(device)}\;,
16
                   create_graph=True, retain_graph=True, only_inputs=True)[0]
17
loss = -(torch.mean(Dp) - torch.mean(Dq) -
            gp\_coeff*torch.mean((gradients.norm(2, dim=1) - 1) ** 2))
20 loss.backward()
optimizer.step()
```

3. In this example we compare the properties of JSD and WD. Given a random variable  $Z \sim U[0,1]$ , we compute the approximation of both metrics between the 2-dimensional distributions, p given by (0, Z), and  $q_{\phi}$  given by  $(\phi, Z)$ , where  $\phi$  is a parameter. In Figures 1 and 2 we plot the estimated JSD and WD respectively for  $\phi \in [-1,1]$  with interval of 0.1. We perform the estimation by optimizing the MLP as in points 1 and 2. We use batches of samples from the distributions of 512, and the models were trained for 5000 iterations using an SGD optimizer. For every value of  $\phi$  we generate the distribution  $q_{\phi}$  and measure its distance to p.

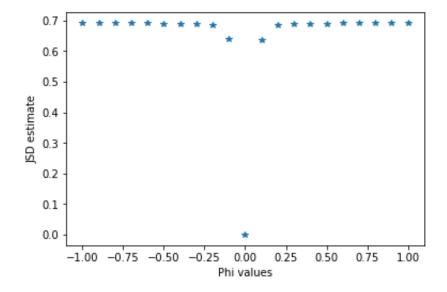

Figure 1: JSD estimation

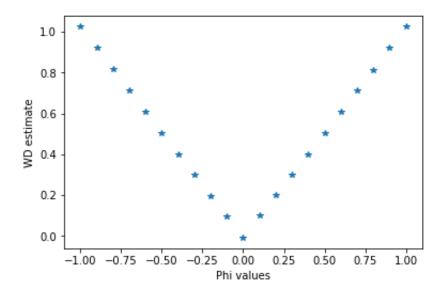

Figure 2: WD estimation

In this experiment the distributions p and  $q_{\phi}$  have disjoint supports for all values of  $\phi$  but  $\phi=0$ . As expected, the JSD when the distributions are disjoint is the same (around  $\log(2)$ ) no matter how close the distributions may be i.e. for a small value of  $\phi$ . This results in a difficulty to learn the distribution p using JSD. In contrast, WD is continuous over the values of  $\phi$  giving a better information about the *closeness* of the distributions.

The full code is given in the file **density\_estimation.py** in our github repository [1].

4. In this section we estimate the unknown density  $f_1$  using the approximation  $f_0(x)D(x)/(1-D(x))$  (proven in Question 5 from the theoretical part), where  $f_0$  is a known distribution (assumed 1-dimensional standard Gaussian in this question). The full code is provided in the file **density\_estimation.py** under our github repository [1].

Using the above neural network (discriminator), we minimize the following function:

```
loss = -(torch.mean(torch.log(Dx)) + torch.mean(torch.log(1 - Dy))),
```

where Dx is the feedforward of  $f_1$  and Dy is the feedforward of  $f_0$ .

The following figures show the discriminator's output and the estimated density:

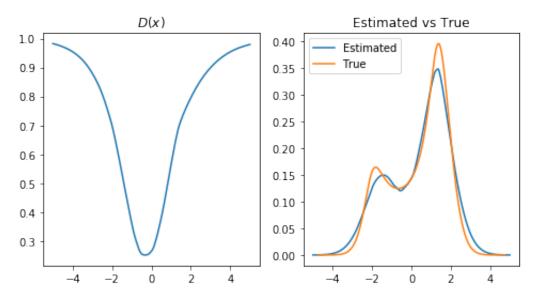

Figure 3: (left) Discriminator output (Right)Estimated  $f_1$ 

## Problem 2

### A. Training VAE

We used the given architecture and ADAM with the provided learning rate. After training the model for 20 Epochs, we achieved an average value of ELBO of -95 on validation set. It is clearly higher than the reference value provided in question.

B.1 Evaluating log-likelihood with VAE

Here we implement the Importance Sampling procedure that takes as parameters the trained model, an array of  $x_i$  and an array of samples  $z_{ik}$  from the distribution  $q(z|x_i)$ . The procedure returns an array of log-likelihood  $\log p(x_i)$  of the size of the mini-batches. The code snippet below demonstrates our implementation.

```
def loss_IS(model, true_x, z):

#Loop over the elements i of batch
M = true_x.shape[0]

#Save logp(x)
```

```
logp_x = np.zeros([M])
7
    #Get mean and std from encoder
9
    #2 Vectors of 100
10
    mu, logvar = model.encode(true_x.to(device))
11
12
    std = torch.exp(0.5*logvar)
13
    K = 200
14
    #Loop over tha batch
16
    for i in range (M):
17
18
      #z_ik
      samples = z[i,:,:]
19
20
      #Compute the reconstructed x's from sampled z's
21
      x = model.decode(samples.to(device))
22
23
      \#Compute the p(x_i|z_ik) of x sampled from z_ik
24
      #Bernoulli dist = Apply BCE
25
      #Output an array of losses
26
       true_xi = true_x[i,:,:].view(-1, 784)
27
       x = x.view(-1, 784)
28
29
       p_{-}x \; = \; true_{-}xi \; * \; torch.log (x) \; + \; (1.0 - true_{-}xi) \; * \; torch.log (1-x)
30
31
       p_x = torch.sum(-p_x, dim=1)
32
33
       s = std[i, :].view([std.shape[1]])
34
      m = mu[i, :]. view([std.shape[1]])
35
       q_z = multivariate_normal.pdf(samples.cpu().numpy(),mean=m.cpu().numpy(),
36
        cov=np.diag(s.cpu().numpy()**2))
37
38
      ##p(z_ik) follows a normal dist with mean 0/variance 1
      \#(64, 100)
39
      #Normally distributed with loc=0 and scale=1
40
       std_1 = torch.ones(samples.shape[1])
41
      mu_0 = torch.zeros(samples.shape[1])
42
43
       p_z = multivariate_normal.pdf(samples.cpu().numpy(),mean=mu_0.cpu().numpy
44
       (), cov=np.diag(std_1.cpu().numpy()**2))
45
      #Multiply the probablities
46
      \#marginal\_likelihood += (p_x * p_z)/q_z
47
      #Use logsumexp trick to avoid very small prob
49
       \log p_x[i] = np.\log((1.0/K) * np.sum(np.exp(np.log(p_x.cpu().numpy()) + np)
50
       .\log(p_z) - np.\log(q_z))
51
  return logp_x
52
```

B.2 The evaluation of the training model using the ELBO:

```
a. Validation: -95
```

b. Test: -94.43

The evaluation of the training model using the log-likelihood:

```
a. Validation: -18.41
```

b. Test: -18.27

Below (Figure 4) is a sample of the obtained images generated by the trained model:

Figure 4: A sample of generated images

## Problem 3

We have used in this problem a similar architecture for the VAE's decoder and the GAN's generator which is an MLP with 6 layers, as shown in this code snippet:

```
class Generator(nn.Module):
       def __init__(self):
           super(Generator, self).__init__()
3
4
           self.model = nn.Sequential(
               nn.Linear(latent_dim, 128),
6
               nn.ReLU()
               nn. Linear (128, 256),
               nn.ReLU()
9
10
               nn. Linear (256, 512),
               nn.ReLU()
               nn. Linear (512, 1024),
12
13
               nn.ReLU()
               nn. Linear (1024, 2048),
14
15
               nn.ReLU()
               nn.Linear(2048, int(np.prod(img_shape))),
16
17
               nn.Tanh()
18
           )
19
       def forward(self, z):
20
21
           img = self.model(z)
           img = img.view(img.shape[0], *img.shape)
22
23
           return img
```

We have decided to go with this architecture, after having tested several architectures for both models, including convolutionnal neural network. We noticed that the VAE model works

fine with a convolutional architecture whereas the GAN have not got good result with that kind of architecture. Both models have been trained with a latent variable dimension of 100.

## A. Qualitative Evaluations

### 1. Visual samples

We have generated different samples from both models (Figures 5 and 6). We notice that the images generated by the VAE seem realistic albeit blurry, whereas the images generated by GAN are more diversified, and seem less realistic.

Figure 5: Samples generated with VAE

Figure 6: Samples generated with GAN.

2. Learning the disentangled representation in the latent space The following figures show how the GAN has learned a desentagled representation:

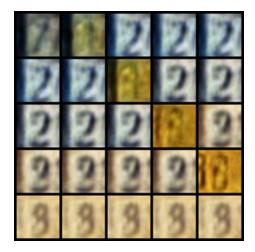

Figure 7: Samples by perturbating dimensions 6 and 96

Figure 8: Samples by perturbating dimensions 25 and 75

## TO BE CONTINUED BY FARRIS FOR VAE

3. Interpolation in the data space and in the latent space: TBD BY JORGE FOR GAN AND FARRIS FOR VAE

### B. Quantitative Evaluations

1. We have used the provided functions to extract the representations of the images. We compute the Frechet Inception Distance by estimating the mean and covariance of the generator's/decoder's distribution. The calculation steps are explained in the following code snippet:

```
def calculate_fid_score(sample_feature_iterator,
                            testset_feature_iterator):
2
       gen_features = np.array([])
3
       test_features = np.array([])
5
       print("Extracting the features ...")
6
      #sample_feature_iterator is a generator of a minibatch of features
      images
      #that is the last conv2d layer of the classifier of 512 features
8
9
      #For generated images
10
       gen_size=0
       for i in sample_feature_iterator: #iterate over minibatch images
12
          #Now let's get the activation of the images
13
           gen_features = np.vstack([gen_features,i.reshape(1,512)]) \
14
           if gen_features.size else i.reshape(1,512)
15
           gen_size+=1
16
17
           if gen_size==1000: break
       gen\_features = gen\_features.T
18
19
      #For test images
20
21
       test_size=0
       for i in testset_feature_iterator: #iterate over test images
22
           test_features = np.vstack([test_features,i.reshape(1,512)])
23
24
           t e s t _s i z e +=1
           if test_size==1000: break
25
       test\_features = test\_features.T
26
27
       print("Estimating the mean ...")
28
      #Estimating the mean of the generated images
29
30
       mu_gen = np.mean(gen_features,axis=1).reshape(512,1)
31
32
      #Estimating the mean of the test images
       mu_test = np.mean(test_features, axis=1).reshape(512,1)
33
34
       print("Estimating the variance ...")
35
      # We use the unbiased variance estimate which
36
      \#is given by (X-mu)(X-mu)^T/(n-1)
37
      gen_centered = gen_features - mu_gen
38
       test_centered = test_features - mu_test
39
40
       sigma_gen = np.matmul(gen_centered, gen_centered.T) / (gen_size - 1)
41
      sigma\_test \ = \ np.matmul(test\_centered \ , \ test\_centered \ .T) \ / \ (test\_size
42
      -1)
43
      print("Calculating the sqrt of cov matrices product ...")
44
      # The sqrt of a matrix A needs A to be symetric, but if A, and B
      # are sysmetric A.B is not symetric necessarly.
46
      # To solve that we use this trick:
47
48
      # sqrt(sigma1 sigma2) = sqrt(A sigma2 A), where A = sqrt(sigma1)
      # the covariance matrix are by definition symetric
49
50
      # to prevent negative values in the cov product
51
      eps = np.eye(512) * 1e-5
52
53
       root_sigma_gen = linalg.sqrtm(sigma_gen + eps)
54
       sigmas_prod = np.matmul(root_sigma_gen, np.matmul(sigma_test,
55
      root_sigma_gen))
      \# \ given \ np.matmul(root\_sigma\_gen, np.matmul(sigma\_test,
56
       root_sigma_gen)) is symetric:
       root_sigmas_prod = linalg.sqrtm(sigmas_prod + eps)
58
```

```
print("Calculating the FID score ...")
       # Calculating the trace
60
       trace = np.trace(sigma_test + sigma_gen - 2.0 * root_sigmas_prod)
61
62
       \# Calculate the squared norm between means
63
       squared_norm = np.sum((mu_test - mu_gen)**2)
64
65
       # Calculate the fid score
fid = squared_norm + trace
66
67
68
      return fid
```

- 2. We sampled 1000 images from each generative models and calculate the FID-score as instructed. The results are:
  - For the GAN, the FID score is: 29526.37
  - For the VAE, the FID score is: 51355.12

This metric confirme our ascertainment that the GAN is more realistic than the VAE, given the ground truth given by the provided classifier.
